1.1 Goals

\$

### **Preliminaries**

#### 2.1 Agda

Agda is a dependently typed functional programming language. The current version<sup>1</sup> was originally developed by Ulf Norell under the name Agda2 [Nor07]. Due to its type system Agda can be used as a programming language and as a proof assistant.

This section contains a short introduction to Agda, dependent types and the idea of "Propositions as types" under which Agda can be used for theorem proving.

Agdas syntax is similar to Haskells. Data types are declared with syntax similar to Haskells GADTs. Functions declarations and definitions are also similar to Haskell, except that Agda uses a single colon for the typing relation. In the following definition of  $\mathbb{N}$ , Set is the type of all (small) types.

```
data \mathbb{N}: Set where zero : \mathbb{N} suc : \mathbb{N} \to \mathbb{N}
```

Ordinary function definition are syntactically similar to Haskell. Agda allows the definition of mixfix operators. A mixfix operator is an nearly arbitrary list of symbols (builtin symbols like colons are not allowed as part of operators). Underscores in the operator name are placeholders for future parameters. A mixfix operator can be applied partially by writing underscores for the omitted parameters.

In the following definition of plus for natural numbers + is a binary operator and therefore containers two underscores.

```
_+_ : \mathbb{N} \to \mathbb{N} \to \mathbb{N}
zero + m = m
suc n + m = \operatorname{suc}(n + m)
```

#### 2.1.1 Dependent Types

The following type theoretic definitions are taken from the homotopy type theory book [Uni13]. In type theory a type of types is called a universe. Universes are usually denoted  $\mathcal{U}$ . A function whose codomain is a universe is called a type family or dependent type.

```
F:A \to \mathcal{U} where B(a):\mathcal{U} for a:A
```

To avoid Russell's paradox, a hierarchy of universes  $\mathcal{U}_1:\mathcal{U}_2:...$  is introduced. Usually the universes are cumulative, i.e. if  $\tau:\mathcal{U}_n$  then  $\tau:\mathcal{U}_k$  for k>n. by default this is not the case in Agda. Each type is member of a unique universe, forcing us to do additional bookkeeping. Since Agda 2.6.1 an experimental --cumulativity flag exists.

<sup>1</sup>https://github.com/agda/agda

5 2.1. AGDA

Dependent Function Types ( $\Pi$ -Types) are a generalization of function types. The codomain of a  $\Pi$  type is not fixed, but values with the argument the function is applied to. The codomain is defined using a type family of the domain, which specifies the type of the result for each given argument.

$$\prod_{a:A} B(a) \quad \text{with} \quad B:A \to \mathcal{U}$$

An element of the above type is a function which maps every a:A to a b:B(a). In Agda the builtin function type  $\Rightarrow$  is a  $\Pi$ -type. An arguments can be named by replacing the type  $\tau$  with a  $x:\tau$ , allowing us to use the value as part of later types.

**Dependent Sum Types (\Sigma-Types)** are a generalization of product types. The type of the second component of the product is not fixed, but varies with the value of the first.

$$\sum_{a:A} B(a) \quad \text{with} \quad B:A \to \mathcal{U}$$

An element of the above type is a pair consisting of an a:A and a b:B(a). In Agda records represent n-ary  $\Sigma$ -types. Each field can be used in the type of the following fields.

**Programming with Dependent Types** A common example for dependent types are fixed length vectors. The data type depends on a type A and a value of type N.

```
\begin{array}{l} \mathsf{data} \ \mathsf{Vec} \ (A : \mathsf{Set}) : \ \mathbb{N} \to \mathsf{Set} \ \mathsf{where} \\ \underline{\quad} :: \underline{\quad} : \ \{n : \ \mathbb{N}\} \to A \to \mathsf{Vec} \ A \ n \to \mathsf{Vec} \ A \ (\mathsf{suc} \ n) \\ \boxed{\mid} \quad : \ \mathsf{Vec} \ A \ 0 \end{array}
```

Arguments on the left-hand side of the colon are called parameters and are the same for all constructors. Arguments on the right-hand side of the colon are called indices an can differ for each constructor. Therefore  $Vec\ A$  is a family of types indexed by  $\mathbb{N}$ .

The [] constructor allows us to create an empty vector of any type, but forces the index to be zero. The \_::\_ constructor appends an element to the front of a vector of the same type, increasing the index in the process. Only these two constructors can be used to construct vectors. Therefore the index is always equal to the amount of elements stored in the vector.

By encoding more information about the data in its type we can add extra constraints to functions working with it. The following definition of head avoids error handling or partiality by excluding the empty vector as a valid argument.

```
\begin{array}{l} \mathsf{head} : \ \forall \ \{A \ n\} \to \mathsf{Vec} \ A \ (\mathsf{suc} \ n) \to A \\ \mathsf{head} \ (x :: \_) = x \end{array}
```

When pattern matching on the argument of head there is no case for []. The argument has type  $Vec\ A\ (suc\ n)$  and [] has type  $Vec\ A\ 0$ . Those to types cannot be unified, because suc and zero are different constructors of  $\mathbb N$ . Therefore, the [] case does not apply. By constraining the type of the function we were able to avoid the case, which usually requires error handling or introduces partiality.

We can extend this idea to type safe indexing. A vector of length n is indexed by the first n natural numbers. The type Fin n represents the subset of natural numbers smaller than n.

```
\begin{array}{l} \mathsf{data} \; \mathsf{Fin} : \; \mathbb{N} \to \mathsf{Set} \; \mathsf{where} \\ \mathsf{zero} : \; \{n : \; \mathbb{N}\} \to \mathsf{Fin} \; (\mathsf{suc} \; n) \\ \mathsf{suc} \; : \; \{n : \; \mathbb{N}\} \to \mathsf{Fin} \; n \to \mathsf{Fin} \; (\mathsf{suc} \; n) \end{array}
```

Because 0 is smaller than every positive natural number, zero can only be used to construct an element of Fin (suc n) i.e. for every type except Fin  $\theta$ .

If any number is smaller than n, then its successor is smaller than n + 1. Therefore, if any number is an element of Fin n then its successor is an element of Fin (suc n).

So we can construct a k < n of type Fin n by starting with zero of type Fin (n - k) and applying suc k times. Using this definition of the bounded subsets of natural numbers we can define  $\_!\_$  for vectors.

Notice that similar to head there is no case for []. n is used as index for Vec A and Fin. The constructors for Fin only use suc, therefore the type Fin zero is not inhabited and the cases for [] do not apply.

By case splitting on the vector first we could have obtained the term [] !i. By case splitting on i we notice that no constructor for Fin zero exists. Therefore, this case cannot occur, because the type of the argument is uninhabited. It's impossible to call the function, because we cannot construct an argument of the correct type. In this example we can either omit the case or explicitly state that the argument is impossible to construct, by replacing it with (), allowing us to omit the definition of the right-hand side of the equation.

```
! () -- no right-hand side
```

The other two cases are straightforward. For index zero we return the hard of the vector. For index suc i we call  $_!$ \_ recursively with the smaller index and the tail of the vector. Notice that the types for the recursive call change. The tail of the vector xs and the smaller index i are indexed over the predecessor of n.

#### 2.1.2 Propositions as Types

An more in depth explanation and an overview over the history of the idea can be found in Wadlers paper of the same name [Wad15].

FOL	MLTT	m Agda
$\forall x \in A : P(x)$	$\Pi_{x:A}P(x)$	$(x : A) \rightarrow P x$
$\exists x \in A : P(x)$	$\Sigma_{x:A}P(x)$	$\Sigma[x \in A] P x mit_,_: (x : A) \rightarrow P x \rightarrow \Sigma A P$
$P \wedge Q$	$P \times Q$	$A \times B$
$P \lor Q$	P+Q	$A \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \ \$
$P \Rightarrow Q$	$P \to Q$	A → B
${f t}$	1	tt : T
${f f}$	0	$\perp$

#### 2.1.3 Termination Checking

The definition of non-terminating functions entails logical inconsistency. Agda therefore only allows the definition terminating functions. Due to the Undecidability of the halting problem Agda uses a heuristic termination checker. The termination checker proofs termination by observing structural recursion. Consider the following definitions of List and map.

The [] case does not contain a recursive calls. In the  $\_::\_$  case the recursive call to map occurs on a structural smaller argument i.e. xs is a subterm of the argument x::xs. Because elements of List A are finite the function map terminates for every argument.

#### Sized Types

7 2.1. AGDA

#### 2.1.4 Strict Positivity

In a type system with arbitrary recursive types, it is possible to to implement a fixpoint combinator and therefore non terminating functions without explicit recursion. As explained in section 2.1.3 this entails logical inconsistency. Agda allows only strictly positive data types. A data type D is strictly positive if all constructors are of the form

$$A_1 \to A_2 \to \cdots \to A_n \to D$$

where  $A_i$  is either not inductive (does not mention D) or are of the form

$$A_1 \to B_2 \to \cdots \to B_n \to D$$

where  $B_j$  is not inductive. By restricting recursive occurrences of a data type in its definition to strict positive positions strong normalization is preserved.

#### Container

Because of the strict positivity requirement it is not allowed to apply generic type constructors to inductive occurrences of a data type in its definition. The reason for this restriction is that a type constructor is not required to use its argument only in strictly positive positions. To still work generically with type constructors or more precise functors we need a more restrictive representation, which only uses its argument in a strictly positive position. One representation of such functors are containers.

Containers are a generic representation of data type, which store values of an arbitrary type. They were introduced by Abbott, Altenkirch and Ghani [AAG03]. A container is defined by a type of shapes S and a type of positions for each of its shapes  $P:S\to\mathcal{U}$ . Usually containers are denoted  $S\rhd P$ . A common example are lists. The shape of a list is defined by its length, therefore the shape type is  $\mathbb{N}$ . A list of length n has exactly n places or positions containing data. Therefore, the type of positions is  $\Pi_{n:\mathbb{N}}\mathrm{Fin}\ n$  where  $\mathrm{Fin}\ n$  is the type of natural numbers smaller than n. The extension of a container is a functor  $[S\rhd P]$ , whose lifting of types is given by

$$[\![S\rhd P]\!]\;X=\sum_{s:S}Ps\to X.$$

A lifted type corresponds to the container storing elements of the given type e.g.  $[\![ \mathbb{N} \triangleright Fin ]\!] A \cong$  List A. The second element of the dependent pair sometimes called position function. It assigns each position a stored value. The functors action on functions is given by

$$\llbracket S \rhd P \rrbracket \ f \langle s, pf \rangle = \langle s, f \circ pf \rangle.$$

We can translate these definition directly to Agda. Instead of a data declaration we can use record declarations. Similar to other languages records are pure product types. A record in Agda is an *n*-ary dependent product type i.e. the type of each field can contain all previous values.

```
record Container : \mathsf{Set}_1 where constructor \_\triangleright\_ field Shape : \mathsf{Set} Pos : \mathsf{Shape} \to \mathsf{Set} open Container public
```

As expected, a container consists of a type of shapes and a dependent type of positions. Notice that  $\mathsf{Container}$  is an element of  $\mathsf{Set}_1$ , because it contains a type from  $\mathsf{Set}$  and therefore has to be larger. Next we define the lifting of types i.e. the container extension, as a function between universes.

```
open import Data.Product using (\Sigma-syntax; __,_) -- TODO: define and explain earlier open import Function using (_\circ_) [_]: Container \to Set \to Set [S \rhd P] A = \Sigma[s \in S] (P \circ S \to A)
```

Using this definition we can define fmap for containers.

```
\begin{array}{l} \mathsf{fmap}: \ \forall \ \{A \ B \ C\} \to (A \to B) \to (\llbracket \ C \, \rrbracket \ A \to \llbracket \ C \, \rrbracket \ B) \\ \mathsf{fmap} \ f \ (s \ , \ p \! f) = (s \ , \ f \circ \ p \! f) \end{array}
```

#### 2.2 Curry

Curry [HKM95] is a functional logic programming language. It combines paradigms from functional programming languages like Haskell with those logical languages Prolog. Curry is based on Haskell i.e. its syntax and semantics not involve nondeterminism closely resemble Haskell. Curry integrates logical features, such as nondeterminism and free variables with a few additional concepts.

When defining a function with overlapping patterns on the left-hand side of equations all matching right-hand sides are executed. This introduces non determinism. The simplest example of such a function is the choice operator ?.

```
(?) :: A -> A -> A
x ? _ = x
_ ? y = y
```

Both equations always match, therefore both arguments are returned i.e. ? introduces a nondeterministic choice between its two arguments. Using choice we can define a simple nondeterministic program.

```
coin :: Int
coin = 0 ? 1

twoCoins :: Int
twoCoins = coin + coin
```

coin chooses non-deterministically between 0 and 1. Executing coin therefore yields these two results. When executing twoCoins the two calls of coin are independent. Both choose between 0 and 1, therefore twoCoins yields the results 0, 1, 1 and 2.

#### Call-Time-Choice

Next we will take a look at the interactions between nondeterminism and function calls.

```
double :: Int -> Int
double x = x + x

doubleCoin :: Int
doubleCoin = double coin
```

When calling double with a nondeterministic value two behaviors are conceivable. The first possibility is that the choice is moved into the function i.e. both  $\mathbf{x}$  chose independent of each other yielding the results 0, 1, 1 and 2. The second possibility is choosing a value before calling the function and choosing between the results for each possible argument. In this case both  $\mathbf{x}$  have the same value, therefore the possible results are 0 and 2. This option is called Call-Time-Choice and it is the one implemented by Curry.

9 2.2. CURRY

Similar to Haskell, Curry programs are evaluated lazily. The evaluation of an expression is delayed until its result is needed and each expression is evaluated at most once. The later is important when expressions are named and reused via let bindings or lambda abstraction. The named expression is evaluated the first time it is needed. If the result is needed again the old value is reused. This behavior is called sharing. Usually function application is defined using the let primitive. Applying a non variable expression to a function introduces a new intermediate result, which bound using let.

$$(\lambda x.\sigma)\tau = \text{let } y = \tau \text{ in } \sigma[x \mapsto y]$$

We therefore expect a variable bound by a let to behave similar to one bound by a function. This naturally extends Call-Time-Choice to let-bindings in lazily evaluated languages.

```
sumCoin :: Int
sumCoin = let x = coin in x + x
```

As expected this function yields the results 0 and 1.

#### **Permutation Sort**

Introduce Free Variables + Explain for Later Example

## Algebraic Effects

Algebraic effects are computational effects, which can be described using an algebraic theory.

Section 3.1 gives a concrete definition for algebraic effects. Section 3.2 describes the implementation using free monads in Agda. The following sections describe the implementation of unscoped and scoped effects in the fist order setting. The scoped effects are implemented using explicit scope delimiters as described by Wu et al. [WSH14].

#### 3.1 Definition

Needed? A la Bauer? Adapts nicely to containers, but I'm not sure how well it works wth scoped syntax and the HO approach

#### 3.2 Free Monads

The syntax of an algebraic effect is described using the free monad. The usual definition of the free monad is Haskell is the following.

As the name suggests, the free monad is the free object in the category of monads, therefore the following holds.

- 1. For every (endo)functor F the functor Free F is a monad
- 2. For every natural transformation from an (endo) functor  ${\cal F}$  to a monad  ${\cal G}$  exists a monad homomorphism from Free  ${\cal F}$  to  ${\cal G}$
- 3. As a consequence of (2) taking the natural transformation to be the identity on F, for every monad exists a monad homomorphism from a Free monad.
- 4. The Free functor is left adjoint and therefore preserves coproducts i.e. Free  $F \oplus Free \ G \cong Free \ (F \oplus G)$

When defining the free monad in Agda we cannot use an arbitrary functor as in Haskell, because it would violate the strict positivity requirement. Instead we will represent the functor as the extension of a container as described in section 2.1.4.

```
\begin{array}{ll} \textbf{data} \ \mathsf{Free} \ \ (C: \mathsf{Container}) \ (A: \mathsf{Set}) : \mathsf{Set} \ \mathsf{where} \\ \mathsf{pure} : \ A \to \mathsf{Free} \ \ C \ A \\ \mathsf{impure} : \ \llbracket \ C \ \rrbracket \ (\mathsf{Free} \ \ C \ A) \to \mathsf{Free} \ \ C \ A \end{array}
```

11 3.2. FREE MONADS

The free monad represents an arbitrary branching tree with values of type A in its leafs. The pure constructor builds leafs containing just a value of type A. The impure constructor takes a value of the Free monad lifted by the container functor of C. Based on the choice of container the actual value could contain an arbitrary number of values i.e. Free monads or subtrees. Furthermore for each shape from the Shape type the number of subtrees can differ or contain additional arbitrary values. The container has no access to the type parameter of the free monad.

The  $\gg$  operator for free monads traverses the trees and applies the continuation to the values stored in the leafs, replacing them.  $\gg$  therefore substitutes leafs with new subtrees generated from the values stored in each leaf.

#### 3.2.1 Functors à la carte

When modelling effects each functor represents the syntax i.e. the operations of an effect. For containers each shape corresponds to an operation symbol and the type of position for a shape corresponds to the arity set for the operation. The additional parameter of an operation is embedded in the shape. The free monad over a container describes a program using the effects syntax i.e. its the free model for the algebra without the equations. To combine the syntax of multiple effects we can combine the underlying functors, because the free monad preserves coproducts.

The approach described by Wu et al. is based on "Data types à la carte" [Swi08]. The functor coproduct is modelled as the data type data (f :+: g) a = Inl (f a) | Inr (g a), which is a Functor in a.

In Agda functors are represented as containers, a concrete data type not a type class. The coproduct of two containers F and G is the container whose shape is the disjoint union of Fs and Gs shapes and whose position function pos is the coproduct mediator of Fs and Gs position functions.

```
\_\oplus\_: \mathsf{Container} \to \mathsf{Container} \to \mathsf{Container} \\ (\mathit{Shape}_1 \rhd \mathit{Pos}_1) \oplus (\mathit{Shape}_2 \rhd \mathit{Pos}_2) = (\mathit{Shape}_1 \uplus \mathit{Shape}_2) \rhd [\mathit{Pos}_1 , \mathit{Pos}_2]
```

The functor represented by the coproduct of two containers is isomorphic to the functor coproduct of their representations. The container without shapes is neutral element for the coproduct of containers. This allows us to define n-ary coproducts for containers.

```
\begin{array}{l} \mathsf{sum} : \mathsf{List} \ \mathsf{Container} \to \mathsf{Container} \\ \mathsf{sum} = \mathsf{foldr} \ (\_ \oplus \_) \ (\bot \rhd \lambda()) \end{array}
```

To generically work with arbitrary coproducts of functors we will define two utility functions. Given a value x:A we want to be able to inject it into any coproduct mentioning A. Given any coproduct mentioning A we want to be able to project a value of type A from the coproduct, if A is the currently held alternative.

In the "Data types à la carte" [Swi08] approach the type class :<: is introduced. :<: relates a functor to a coproduct of functors, marking it as an option in the coproduct. :<:s functions can be used to inject values into or maybe extract values from a coproduct. The two instances for :<: mark F as an element of the coproduct if it's an on the left-hand side of the coproduct (in the head) or if it's already in the right-hand side (in the tail).

```
class (Syntax sub, Syntax sup) => sub :<: sup where
  inj :: sub m a -> sup m a
  prj :: sup m a -> Maybe (sub m a)

instance {-# OVERLAPPABLE #-} (Syntax f, Syntax g) => f :<: (f :+: g) where
  inj = Inl
  prj (Inl a) = Just a
  prj _ = Nothing

instance {-# OVERLAPPABLE #-} (Syntax h, f :<: g) => f :<: (h :+: g) where
  inj = Inr . inj
  prj (Inr ga) = prj ga
  prj _ = Nothing</pre>
```

The two instances overlap resulting in possible slower instance resolution. Furthermore, :+: is assumed to be right associative and only to be used in a right associative way to avoid backtracking.

Because in Agda the result of  $\_\oplus\_$  is another container, not just a value of a simple data type, instance resolution using  $\_\oplus\_$  is not as straight forward as in Haskell and in some cases extremely slow<sup>1</sup>.

This implementation of the free monad uses an approach similar to the Idris effect library [Bra13]. The free monad is not parameterised over a single container, but a list ops of containers. This has the benefit that we cannot associate coproducts to the left by accident. The elements of the list are combined later using sum. To track which functors are part of the coproduct we introduce the new type  $\_ \in \_$ .

```
data _\in_ {\ell : Level} {A : Set \ell} (x : A) : List A \to \mathsf{Set}\ \ell where instance here : \forall {xs} \to x \in x :: xs there : \forall {y xs} \to {x \in xs} \to x \in y :: xs
```

The type  $x \in xs$  represents the proposition that x is an element of xs. The two constructors can be read as rules of inference. One can always construct a proof that x is in a list with x in its head and given a proof that  $x \in xs$  one can construct a proof that x is also in the extended list y :: xs.

The two instances still overlap resulting in  $\mathcal{O}(c^n)$  instance resolution. Using Agdas internal instance resolution can be avoided by using a tactic to infer  $\_\in\_$  arguments. For simplicity the following code will still use instance arguments. This version can easily be adapted to one using macros, by replacing the instance arguments with correctly annotated hidden ones.

Using this proposition we can define functions for injection into and maybe projecting out of coproducts.

```
 \begin{array}{lll} \text{inject}: \ \forall \ \{C \ ops \ \ell\} \ \{A : \mathsf{Set} \ \ell\} \to C \in ops \to \llbracket \ C \, \rrbracket \ A \to \llbracket \ \mathsf{sum} \ ops \, \rrbracket \ A \\ \text{inject here} & (s \ , \ pf) = (\mathsf{inj}_1 \ s) \ , \ pf \\ \text{inject} \ (\mathsf{there} \ \llbracket \ p \, \rrbracket) \ prog & \mathsf{with} \ \mathsf{inject} \ p \ prog \\ \dots \ | \ s \ , \ pf = (\mathsf{inj}_2 \ s) \ , \ pf \\ \text{project}: \ \forall \ \{C \ ops \ \ell\} \ \{A : \mathsf{Set} \ \ell\} \to C \in ops \to \llbracket \ \mathsf{sum} \ ops \, \rrbracket \ A \to \mathsf{Maybe} \ (\llbracket \ C \, \rrbracket \ A) \\ \text{project here} & (\mathsf{inj}_1 \ s \ , \ pf) = \mathsf{just} \ (s \ , \ pf) \\ \text{project there} & (\mathsf{inj}_2 \ \_ \ , \ \_) = \mathsf{nothing} \\ \text{project} \ (\mathsf{there} \ \{ \ p \ \}) \ (\mathsf{inj}_2 \ s \ , \ pf) = \mathsf{project} \ p \ (s \ , \ pf) \\ \end{array}
```

Both inject and project require a proof/evidence that specific container is an element of the list used to construct the coproduct.

Let us consider inject first. By pattern matching on the evidence we acquire more information about type  $sum\ ops$ . In case of here we know that op is in the head of the list i.e. that the given value C is the same as the one in the head of the list. Therefore the Shape types are the same and we can use our given s and pf to construct the coproduct. In case of there we obtain a proof that the container is in the tail of the list, which we can use to make a recursive call. By pattern matching on and repackaging the result we obtain a value of the right type.

project functions similarly. By pattern matching on the proof we either know that the value we found has the correct type or we obtain a proof for the tail of the list allowing us to make a recursive call.

#### 3.2.2 The Free Monad for Effect Handling

Using the coproduct machinery we can now define a version of the free monad, suitable for working with effects. In contrast to the first definition, this free monad is parameterized over a list of containers. In the impure constructor the containers are combined using sum. The parameterization over a list ensures that the containers are not combined prematurely.

```
\begin{array}{l} \textbf{data} \ \mathsf{Free} \ (\mathit{ops} : \mathsf{List} \ \mathsf{Container}) \ (A : \mathsf{Set}) : \ \{\mathsf{Size}\} \to \mathsf{Set} \ \mathsf{where} \\ \mathsf{pure} : \ \forall \ \{i\} \to A \to \mathsf{Free} \ \mathit{ops} \ A \ \{i\} \\ \mathsf{impure} : \ \forall \ \{i\} \to \llbracket \ \mathsf{sum} \ \mathit{ops} \ \rrbracket \ (\mathsf{Free} \ \mathit{ops} \ A \ \{i\}) \to \mathsf{Free} \ \mathit{ops} \ A \ \{\uparrow \ i\} \end{array}
```

 $<sup>^{1}</sup>$ I encountered cases where type checking of overlapping instances involving  $\_\oplus\_$  did not seem to terminate.

13 3.2. FREE MONADS

Next we define utility functions for working with the free monad. inj and prj provide the same functionality as the ones used by Wu el al. inj allows to inject syntax into a program whose signature allows the operation. prj allows to inspect the next operation of a program, restrict to a specific signature. Furthermore we add the functions op and upcast. op generates the generic operation for any operation symbol. upcast transformes a program using any signature to one using a larger signature. Notice that upcast preserves the size of its input, because it just traverses the tree and repackages the contents.

```
\begin{array}{l} \text{inj}: \ \forall \ \{C \ ops \ A\} \rightarrow \{\!\!\{\ C \in ops \ \}\!\!\} \rightarrow [\!\![\ C \ ]\!\!] \ (\mathsf{Free} \ ops \ A) \rightarrow \mathsf{Free} \ ops \ A \\ \mathsf{inj} \ \{\!\!\{\ p \ \}\!\!\} = \mathsf{impure} \circ \mathsf{inject} \ p \\ \\ \mathsf{prj}: \ \forall \ \{C \ ops \ A \ i\} \rightarrow \{\!\!\{\ C \in ops \ \}\!\!\} \rightarrow \mathsf{Free} \ ops \ A \ \{\!\!\uparrow i\} \rightarrow \mathsf{Maybe} \ ([\!\![\ C \ ]\!\!] \ (\mathsf{Free} \ ops \ A \ \{i\})) \\ \mathsf{prj} \ \{\!\!\{\ p \ \}\!\!\} \ (\mathsf{pure} \ x) = \mathsf{project} \ p \ x \\ \\ \mathsf{op}: \ \forall \ \{C \ ops \} \rightarrow \{\!\!\{\ C \in ops \ \}\!\!\} \rightarrow (s: \mathsf{Shape} \ C) \rightarrow \mathsf{Free} \ ops \ (\mathsf{Pos} \ C \ s) \\ \mathsf{op} \ s = \mathsf{inj} \ (s \ , \mathsf{pure}) \\ \\ \mathsf{upcast}: \ \forall \ \{C \ ops \ A \ i\} \rightarrow \mathsf{Free} \ ops \ A \ \{i\} \rightarrow \mathsf{Free} \ (C:: ops) \ A \ \{i\} \\ \\ \mathsf{upcast} \ (\mathsf{pure} \ x) = \mathsf{pure} \ x \\ \\ \mathsf{upcast} \ (\mathsf{impure} \ (s \ , \ \kappa)) = \mathsf{impure} \ (\mathsf{inj}_2 \ s \ , \mathsf{upcast} \circ \kappa) \\ \end{array}
```

The free monad is indexed over an argument of Type Size. pure values have an arbitrary size. When constructing an impure value the new value is strictly larger than the ones produced by the containers position function. The size annotation therefore corresponds to the height of the tree described by the free monad. Using the annotation it's possible to proof that functions preserve the size of a value or that complex recursive functions terminate.

Consider the following definition of fmap for the free monad<sup>2</sup>.

```
\begin{array}{ll} \mathsf{fmap} \_ <\!\!\! \$ \_ : \; \{F : \mathsf{List} \; \mathsf{Container}\} \; \{i : \; \mathsf{Size}\} \to (A \to B) \to \mathsf{Free} \; F \; A \; \{i\} \to \mathsf{Free} \; F \; B \; \{i\} \\ f <\!\!\! \$ > \; \mathsf{pure} \; x \qquad \qquad = \; \mathsf{pure} \; (f \; x) \\ f <\!\!\! \$ > \; \mathsf{impure} \; (s \; , \; pf) = \; \mathsf{impure} \; (s \; , \; (f <\!\!\! \$ \searrow \_) \circ pf) \\ \mathsf{fmap} = \_ <\!\!\! \$ \searrow \_ \end{array}
```

fmap applies the given function f to the values stored in the pure leafs. The height of the tree is left unchanged. This fact is wittnessed by the same index i on the argument and return type.

In contrast to fmap, bind does not preserve the size. bind replaces every pure leaf with a subtree, which is generated from the stored value. The resulting tree is therefore at least as high as the given one. Because there is no + for sized types the only correct size estimate for the returned value is "unbounded". The return type is not explicitly indexed, because the compiler correctly inferes  $\infty$ .

```
\begin{tabular}{lll} $\_$>=_: $\forall $\{ops\} \to {\sf Free} \ ops \ A \to (A \to {\sf Free} \ ops \ B) \to {\sf Free} \ ops \ B \\ {\sf pure} \ x &>\!\!\!>= k = k \ x \\ {\sf impure} \ (s \ , \ pf) >\!\!\!>= k = {\sf impure} \ (s \ , \ (\_>\!\!\!>= k) \circ pf) \\ $\_>_: $\forall $\{ops\} \to {\sf Free} \ ops \ A \to {\sf Free} \ ops \ B \to {\sf Free} \ ops \ B \\ $ma>\!\!>= mb = ma >\!\!\!>= \lambda \ \_\to mb \\ \end{tabular}
```

To complete our basic set of monadic functions we also define ap.

 $<sup>^{2}</sup>$ in the following code A, B and C are arbitrary types

#### 3.2.3 Properties

This definition of the free monad is a functor because it satisfies the two functor laws. Both properties are proven by structural induction over the free monad. Notice that to proof the equality of the position functions, in the induction step, the axiom of extensionality is invoked.

$$\begin{array}{ll} \mathsf{fmap-id}: \ \forall \ \{\mathit{ops}\} \to (\mathit{p}: \mathsf{Free} \ \mathit{ops} \ A) \to \mathsf{fmap} \ \mathsf{id} \ \mathit{p} \equiv \mathit{p} \\ \mathsf{fmap-id} \ (\mathsf{pure} \ \mathit{x}) &= \mathsf{refl} \\ \mathsf{fmap-id} \ (\mathsf{impure} \ (\mathit{s} \ , \mathit{pf})) = \mathsf{cong} \ (\mathsf{impure} \ \circ \ (\mathit{s} \ , \underline{\ })) \ (\mathsf{extensionality} \ (\mathsf{fmap-id} \ \circ \ \mathit{pf})) \end{array} \tag{1}$$

$$\begin{array}{ll} \mathsf{fmap}\text{-}\circ: \ \forall \ \{\mathit{ops}\} \ (f\colon B \to C) \ (g\colon A \to B) \ (p\colon \mathsf{Free} \ \mathit{ops} \ A) \to \\ & \mathsf{fmap} \ (f\circ g) \ p \equiv (\mathsf{fmap} \ f\circ \mathsf{fmap} \ g) \ p \\ \mathsf{fmap}\text{-}\circ f \ g \ (\mathsf{pure} \ x) & = \mathsf{refl} \\ \mathsf{fmap}\text{-}\circ f \ g \ (\mathsf{impure} \ (s\ , \mathit{pf})) = \mathsf{cong} \ (\mathsf{impure} \ \circ \ (s\ , \underline{\ \ })) \ (\mathsf{extensionality} \ (\mathsf{fmap}\text{-}\circ \ f \ g \circ \mathit{pf})) \end{array}$$

This definition of the free monad also satisfies the three monad laws.

$$\mathsf{bind}\text{-ident}^\mathsf{I}: \ \forall \ \{\mathit{ops}\} \ (f\colon A \to \mathsf{Free} \ \mathit{ops} \ B) \ (x\colon A) \to (\mathsf{pure} \ x \ggg f) \equiv f \ x$$
 
$$\mathsf{bind}\text{-ident}^\mathsf{I} \ f \ x = \mathsf{refl}$$

$$\begin{array}{ll} \mathsf{bind}\text{-}\mathsf{ident}^{\mathsf{r}}: \ \forall \ \{\mathit{ops}\}\ (x: \mathsf{Free}\ \mathit{ops}\ A) \to (x \ggg \mathsf{pure}) \equiv x \\ \mathsf{bind}\text{-}\mathsf{ident}^{\mathsf{r}}\ (\mathsf{pure}\ x) &= \mathsf{refl} \\ \mathsf{bind}\text{-}\mathsf{ident}^{\mathsf{r}}\ (\mathsf{impure}\ (s\ ,\ \mathit{pf})) = \mathsf{cong}\ (\mathsf{impure}\ \circ\ (s\ ,\ \_))\ (\mathsf{extensionality}\ (\mathsf{bind}\text{-}\mathsf{ident}^{\mathsf{r}}\ \circ\ \mathit{pf})) \end{array}$$

$$\begin{array}{l} \mathsf{bind}\text{-assoc}: \ \forall \ \{\mathit{ops}\} \ (f\colon A \to \mathsf{Free} \ \mathit{ops} \ B) \ (g\colon B \to \mathsf{Free} \ \mathit{ops} \ C) \ (p\colon \mathsf{Free} \ \mathit{ops} \ A) \to \\ & ((p\ggg f)\ggg g) \equiv (p\ggg (\lambda \ x \to f \ x\ggg g)) \\ \mathsf{bind}\text{-assoc} \ f \ g \ (\mathsf{pure} \ x) &= \mathsf{refl} \\ \mathsf{bind}\text{-assoc} \ f \ g \ (\mathsf{impure} \ (s\ , \ \mathit{pf})) = \mathsf{cong} \ (\mathsf{impure} \circ (s\ , \ \_)) \ (\mathsf{extensionality} \ (\mathsf{bind}\text{-assoc} \ f \ g \circ \mathit{pf})) \end{array}$$

#### 3.3 Handler

```
run : Free [] A \rightarrow A
run (pure x) = x
```

#### **3.3.1** Nondet

The nondeterminism effect has two operations \_??\_ and fail. \_??\_ introduces a nondeterministic choice between two execution paths and fail discards the current path. We therefore have a nullary and a binary operation, both without additional parameters.

$$\Sigma_{\mathrm{Nondet}} = \{ ??: \mathbf{1} \rightsquigarrow \mathbf{2}, \mathrm{fail}: \mathbf{1} \rightsquigarrow \mathbf{0} \}$$

Expressed as a container we have a shape with two constructors, one for each operation and both without parameters.

```
data Nondet<sup>s</sup>: Set where ??<sup>s</sup> fail<sup>s</sup>: Nondet<sup>s</sup>
```

When constructing the container we assign the correct arities to each shape.

```
\begin{array}{ll} \mathsf{Nondet} : \mathsf{Container} \\ \mathsf{Nondet} = \mathsf{Nondet}^\mathsf{s} \rhd \lambda \ \mathsf{where} \\ ??^\mathsf{s} & \to \mathsf{Bool} \\ \mathsf{fail}^\mathsf{s} \to \bot \\ \end{array}
```

We can now define smart constructors for each operation. These are not the generic operations, but helper functions based on them. The generic operations take no parameters an alaways use pure as continuation. These versions of the operations already process the continuations parameter.

15 3.3. HANDLER

With the syntax in place we can now move on to semantics and define a handler for the effect. By introducing pattern declarations for each operations the handler can be simplified. Furthermore we introduce a pattern for other operations, i.e. those who are not part of the currently handled signature.

```
pattern Other s \kappa = \text{impure } (\text{inj}_2 s, \kappa)
pattern Fail \kappa = \text{impure } (\text{inj}_1 \text{ fail}^s, \kappa)
pattern Choice \kappa = \text{impure } (\text{inj}_1 \ensuremath{\mathscr{R}}^s, \kappa)
```

The handler interprets Nondet syntax and removes it from the program. Therefore Nondet is removed from the front of the effect stack and the result is wrapped in a List. The List contains the results of all successful execution paths.

```
solutions : \forall \{ops\} \rightarrow \mathsf{Free} \; (\mathsf{Nondet} :: ops) \; A \rightarrow \mathsf{Free} \; ops \; (\mathsf{List} \; A)
```

The pure constructor represents a program without effects. The singleton list is returned, because no nondeterminism is used in a pure calculation.

```
solutions (pure x) = pure (x := [])
```

The fail constructor represents an unsuccessful calculation. No result is returned.

```
solutions (Fail \kappa) = pure []
```

In case of a Choice both paths can produce an arbitrary number of results. We execute both programs recursively using solutions and collect the results in a single List.

```
solutions (Choice \kappa) = _++_ \ll solutions (\kappa true) \otimes solutions (\kappa false)
```

In case of syntax from another effect we just execute solutions on every subtree by mapping the function over the container. Note that the newly constructed value has a different type. Since Nondet syntax was removed from the tree the proof for  $\_\in\_$ , which is passed to impure changes.

```
solutions (Other s \kappa) = impure (s, solutions \circ \kappa)
```

#### 3.3.2 State

The state effect has two operations get and put. The whole effect is parameterized over the state type s.

get simply returns the current state. The operation takes no additional parameters and has s positions. This can either be interpreted as get being an s-ary operation (one child for each possible state) or simply the parameter of the continuation being a value of type s.

put updates the current state. The operation takes an additional parameter, the new state. The operation itself is unary i.e. there is no return value, therefore tt is passed to the rest of the program.

$$\Sigma_{State} = \{ \text{get} : \mathbf{1} \rightsquigarrow s, \text{put} : s \rightsquigarrow \mathbf{1} \}$$

As before we will translate this definition in a corresponding container.

```
\begin{array}{l} \mathsf{data} \; \mathsf{State}^\mathsf{s} \; (S : \mathsf{Set}) : \; \mathsf{Set} \; \mathsf{where} \\ \; \mathsf{get}^\mathsf{s} : \; \mathsf{State}^\mathsf{s} \; S \\ \; \mathsf{put}^\mathsf{s} : \; S \to \mathsf{State}^\mathsf{s} \; S \\ \\ \mathsf{State} : \; \mathsf{Set} \to \mathsf{Container} \\ \mathsf{State} \; S = \mathsf{State}^\mathsf{s} \; S \rhd \lambda \; \mathsf{where} \\ \end{array}
```

```
\begin{array}{ll} \operatorname{get^s} & \to S \\ \left(\operatorname{put^s} \_\right) \to \top \\ \\ \operatorname{pattern} \ \operatorname{Get} \ \kappa = \operatorname{impure} \left(\operatorname{inj_1} \ \operatorname{get^s} \ , \ \kappa\right) \\ \operatorname{pattern} \ \operatorname{Put} \ s \ \kappa = \operatorname{impure} \left(\operatorname{inj_1} \left(\operatorname{put^s} \ s\right) \ , \ \kappa\right) \\ \end{array}
```

To simplify working with the **State** effect we add smart constructors. These correspond to the generic operations.

```
\begin{array}{l} \mathsf{get} : \ \forall \ \{ops \ S\} \to \{\!\![\ \mathsf{State} \ S \in ops \ ]\!\!\} \to \mathsf{Free} \ ops \ S \\ \mathsf{get} = \mathsf{inj} \ (\mathsf{get}^\mathsf{s} \ , \ \mathsf{pure}) \\ \\ \mathsf{put} : \ \forall \ \{ops \ S\} \to \{\!\![\ \mathsf{State} \ S \in ops \ ]\!\!\} \to S \to \mathsf{Free} \ ops \ \top \\ \mathsf{put} \ s = \mathsf{inj} \ (\mathsf{put}^\mathsf{s} \ s \ , \ \mathsf{pure}) \end{array}
```

Using these defintions for the syntax we can define the handler for State.

The effect handler for **State** takes an initial state together with a program containing the effect syntax. The final state is returned in addition to the result.

```
\mathsf{runState}: \ \forall \ \{\mathit{ops}\ S\} \to S \to \mathsf{Free}\ (\mathsf{State}\ S :: \mathit{ops})\ A \to \mathsf{Free}\ \mathit{ops}\ (S \times A)
```

A pure calculation doesn't change the current state. Therefore, the initial is also the final state and returned in addition to the result of the caluclation.

```
runState s_0 (pure x) = pure (s_0, x)
```

The continuation/position function for get takes the current state to the rest of the calculation. By applying  $s_0$  to  $\kappa$  we obtain the rest of the computation, which we can evaluate recursively.

```
runState s_0 (Get \kappa) = runState s_0 (\kappa s_0)
```

put updates the current state, therefore we pass the new state  $s_I$  to the recursive call of runState.

```
runState _ (Put s_t \kappa) = runState s_t (\kappa tt)
```

Similar to the handler for Nondet we apply the handler to every subterm of non State operations.

```
runState s_0 (Other s \kappa) = impure (s, runState s_0 \circ \kappa)
```

#### Example

Here is a simple example for a function using the State effect. The function tick returns tt and as side effect increases the state.

```
\begin{array}{l} \mathsf{tick} : \forall \ \{\mathit{ops}\} \to \{\!\!\mid \mathsf{State} \ \mathbb{N} \in \mathit{ops} \ \}\!\!\mid \to \mathsf{Free} \ \mathit{ops} \ \top \\ \mathsf{tick} = \underset{}{\mathsf{do}} \ \mathit{i} \leftarrow \mathsf{get} \ ; \ \mathsf{put} \ (1 + \mathit{i}) \end{array}
```

Using the runState handler we can evaluate programs, which use the State effect.

(run \$ runState 0 \$ tick 
$$\gg$$
 tick)  $\equiv$  (2, tt)

#### **Properties**

#### 3.4 Scoped Effects

- Modularity - Combination of Effects - Semantics choosen by order of handlers - problem with scoping operations and syntax of different effects

To correctly handle operations with local scopes Wu et al. introduced scoped effects [WSH14]. They presented two solutions to explicitly declare how far an operations scopes over a program using arbitrary syntax. In the following section we will implement the scoped effect Cut using the first order approach in Agda. The central idea is to add new effect syntax, representing explicit scope delimiters. Whenever an opening delimiter is encountered the handler can be run on the again on the scoped program.

#### 3.4.1 Cut and Call

First we will define the syntax for the new effect and its delimiters.

```
data Cut<sup>s</sup> : Set where cutfail<sup>s</sup> : Cut<sup>s</sup> data Call<sup>s</sup> : Set where bcall<sup>s</sup> ecall<sup>s</sup> : Call<sup>s</sup> pattern Cutfail = impure (inj<sub>1</sub> cutfail<sup>s</sup> , __) pattern BCall \kappa = impure (inj<sub>1</sub> bcall<sup>s</sup> , \kappa) pattern ECall \kappa = impure (inj<sub>1</sub> ecall<sup>s</sup> , \kappa) Cut Call : Container Cut = Cut<sup>s</sup> \rhd \lambda __ \rightarrow \bot Call = Call<sup>s</sup> \rhd \lambda __ \rightarrow \top
```

The Cut effect has just a single operation, cutfail. cutfail can only be used in a context with nondeterminism. When a cutfail is called it will prunes all unexplored branches and call fail. The Agda implementation of the handlers is identical to the one by Wu et al.

The handler itself calls the function go, which accumulates the unexplored alternatives in its second argument. fail is the neutral element for ?? and therefore the default argument. Since this handler is not orthogonal (i.e it interacts with another effect) Nondet is required to be in scope, but its position is irrelevant.

To prove termination we mark the second argument with an arbitrary but fixed size i. The position functions for each case return subterms indexed with a smaller size. Recursive calls to go with these terms as argument therefore terminate.

```
\begin{array}{l} \mathsf{call} : \; \{ \!\!\! \mid \mathsf{Nondet} \in \mathit{ops} \; \} \!\!\! \rightarrow \mathsf{Free} \; (\mathsf{Cut} :: \mathit{ops}) \; A \to \mathsf{Free} \; \mathit{ops} \; A \\ \mathsf{call} = \mathsf{go} \; \mathsf{fail} \\ \mathsf{where} \\ \mathsf{go} : \; \{ \!\!\! \mid \mathsf{Nondet} \in \mathit{ops} \; \} \!\!\! \rightarrow \mathsf{Free} \; \mathit{ops} \; A \to \mathsf{Free} \; (\mathsf{Cut} :: \mathit{ops}) \; A \; \{i\} \to \mathsf{Free} \; \mathit{ops} \; A \\ \end{smallmatrix}
```

In case of a pure value no cutfail happend. We therefore return a calculation choosing between the value and the earlier separated alternatives.

```
go q (pure a) = (pure a) ?? q
```

In case of a cutfail we terminate the current computation by calling fail and prune the alternatives by ignoring q.

```
go _ Cutfail = fail
```

To interact with Nondet syntax we have to find it. We have a proof that the Nondet effect is an element of the effect list. Whenever we find syntax from another effect we can therefore try to project the Nondet option from the coproduct. Notice that prj hides the structural recursion but decreases the Size index. We can therefore still proof that the function terminates.

```
go q p@(Other s \kappa) with pri {Nondet} p
```

The case for ?? separates the main branch from the alternative. Using go the Cut syntax is removed from both alternatives, but the results are handled asymetrically. The left option is directly passed to the recursive call of go. The handled right option is the new alternative for the left one and therefore could be pruned if left contains a cutfail call.

```
... | just (??s , \kappa ) = go (go q (\kappa false)) (\kappa true)
```

When encountering a fail we continue with the accumulated alternatives.

```
... | just (fail^s , \underline{\phantom{a}} ) = q
```

Syntax from other effects is handled as usuall.

```
\dots \mid \mathsf{nothing} = \mathsf{impure} \ (s \ \mathsf{, go} \ q \circ \kappa)
```

With the handler for Cut in place we can define the handler for the scope delimiters. The implementation is again similar to the one presented by Wu et al., but to proof termination we again have to add Size annotations to the functions.

The bcall and ecall handler remove the scope delimiter syntax from the program and run call (the handler for cut) at the begining of each scope. Whenever a BCall is found the handler ecall is used to handle the rest of the program. ecall searches for the end of the scope and returns the program up to that point. The rest of the program is the result of the returned program.

A valid upper bound for the size of the rest of the program is i, the size of the program before separating the syntax after the closing delimiter. This fact is curcial to proof that the recursive calls to bcall and ecall using  $\gg$  terminate.

Calling the handler on the extracted program guaranties that the handler does not interact with syntax outside the intended scope. Nested scopes are handled using recursive calls to ecall if BCall operations are encountered while searching a closing delimiter.

Since the delimiters could be placed freely it is possible to mismatch them. If we encounter a closing before and operening delimiter, we know that they are mismatched. Wu et al. use Haskells error function to terminate the program. In Agda we are not allowed to define partial functions, therefore we have to handle the error. We could either correct the error and just continue or short circuit the calculation using exceptions in form of e.g. a Maybe monad. For simplicity we will use the former approach. In a real application it would be advisable to inform the programmer about the error, either using exceptions are at least trace the error.

```
\mathsf{bcall}: \{ \{ \mathsf{Nondet} \in \mathit{ops} \} \} \to \mathsf{Free} (\mathsf{Call} :: \mathsf{Cut} :: \mathit{ops}) \ A \ \{i\} \to \mathsf{Free} (\mathsf{Cut} :: \mathit{ops}) \ A \}
ecall : { Nondet \in ops } \rightarrow Free (Call :: Cut :: ops) A \{i\}
  \rightarrow Free (Cut :: ops) (Free (Call :: Cut :: ops) A \{i\})
bcall (pure x)
                       = pure x
bcall (BCall \kappa)
                      = upcast (call (ecall (\kappa tt))) \gg bcall
bcall (ECall \kappa) = bcall (\kappa tt) -- Unexpected ECall! We just fix the error.
bcall (Other s \kappa) = impure (s, bcall \circ \kappa)
ecall (pure x)
                       = pure (pure x)
ecall (BCall \kappa)
                       = upcast (call (ecall (\kappa tt))) \gg ecall
ecall (ECall \kappa)
                       = pure (\kappa tt)
ecall (Other s \kappa) = impure (s, ecall \circ \kappa)
```

Using the handlers defined above we can define a handler for scoped Cut syntax, which removes Cut and Call syntax simultaneously. The delimiters and correctly scoped Cut syntax is removed using bcall and potential unscoped Cut syntax is removed with a last use of call. The function call is a smart constructor for the scope delimiters.

```
\begin{array}{l} \operatorname{runCut}: \{\!\!\{ \text{ Nondet} \in ops \ \!\!\} \to \operatorname{Free} \left( \operatorname{Call} :: \operatorname{Cut} :: ops \right) A \to \operatorname{Free} ops \ A \\ \operatorname{runCut} = \operatorname{call} \circ \operatorname{bcall} \\ \\ \operatorname{call}: \{\!\!\{ \text{ Call} \in ops \ \!\!\} \to \operatorname{Free} ops \ A \to \operatorname{Free} ops \ A \\ \operatorname{call} \ p = \operatorname{do} \operatorname{op} \operatorname{bcall}^{\operatorname{s}} ; \ x \leftarrow p \ ; \operatorname{op} \operatorname{ecall}^{\operatorname{s}} ; \operatorname{pure} \ x \\ \end{array}
```

#### 3.5 Call-Time Choice as Effect

Bunkenburg presented an approach to model call-time choice as a stack of scoped algebraic effects [Bun19]. In this section we will extend the nondeterminism effect from section 3.3.1 to one modelling call-time choice.

The current implementation of Nondet does not support sharing.
